Abstract

Since the radiation from different portions in the central region of a quasar can be successively amplified during a microlensing event, microlensing light curves provide fruitful information regarding the emissivity distribution of an accretion disk located at the quasar center. We present a basic methodology of how to map the emissivity distribution of the disk as a function of the radial distance from the center, $Q(r)$, from ‘observed’ microlens light curves during a caustic crossing event. Our proposed method is based on the standard inversion technique, the so-called regularization method, and Abel’s transformation of the one-dimensional luminosity profile integrated along the line parallel to the caustics. This technique will be used to map the disk structure in Q2237+0305, for which the HST and AXAF observations are scheduled. A reconstruction of the image on length scales of several to ten AUs is quite feasible for this source, as long as the measuring errors are within 0.02 mag and the observation time intervals are one week or less.

Key words: Accretion disks — Active Galactic Nuclei — Black Holes — Microlensing — Quasars: individuals (Q2237+0305)

1. Introduction

In many cases of astrophysical objects, their direct images are too small to resolve with the usual telescopes. In the case of a quasar accretion disk, for example, its angular size is, typically, on the order of $\theta_d \sim 0.01\text{pc}/1\text{Gpc} = 10^{-11}\text{rad} \approx 1\mu\text{as}$. In the case of a binary accretion disk, on the other hand, we estimate $\theta_d \sim 3 \times 10^{10}\text{cm}/1\text{kpc} = 10^{-11}\text{rad} \approx 1\mu\text{as}$. These are both considerably below the angular resolution of any present-day telescopes. What is usually attempted is, therefore, to construct theoretical models based on the basic equations of (magneto)hydrodynamics and to infer their structure from the limited number of information, such as the total radiation output originating from their entire surface at some wavelength bands.

In some special cases, however, we can ‘resolve’ the spatial structure of the disk by using a ‘natural’ telescope. A good example is the technique of eclipse mapping (Horne 1985). Since a certain fraction of an accretion disk is shadowed by a companion star in an eclipsing close binary and since the shadowed part varies with time in accordance with the orbital phase, we can map the disk emissivity distribution from the eclipsing light curves. A variety of disk luminosity profiles has been revealed with this technique and our knowledge about the disk structure has been remarkably enriched. Unfortun-

nately, however, this technique is irrelevant to probing a quasar accretion-disk structure because there are no eclipsing objects known to date (see, however, McKernan, Yaqoob 1998).

An alternative and potentially powerful method using a microlensing phenomenon has been considered. Chang and Refsdal (1979, 1984) considered flux changes that might occur due to gravitational lensing by a single star in an extended gravitational lens galaxy. Now, a stimulating discussion has started that such a microlensing phenomenon can be used to investigate the quasar central structure (Grieger et al. 1988; Rauch, Blandford 1991) as a ‘gravitational telescope’ (Blandford, Hogg 1995). The Einstein Cross, Q2237+0305 (e.g., Huchra et al. 1985), is the first object in which quasar microlensing events were detected (Corrigan et al. 1991, Houde, Racine 1994, see also Ostensen et al. 1996). These observations suggest that microlensing events seem to take place almost every year. This rather high frequency is consistent with the microlens optical depth of $\tau \simeq 0.2 - 0.8$ obtained by a realistic simulation of the lensing galaxy (i.e., Wambsganss, Paczyński 1994).

We, here, specifically consider the microlensing event of this source caused by the so-called ‘caustic crossings.’ Several authors have already calculated and inspired this ‘caustic’ case based on simple disk models (e.g., Wambsganss, Paczyński 1991; Jaroszyński et al. 1992) or recently on the realistic disk models (Yonehara et al. 1998, 1999). All of these calculations correspond to the so-

* Research Fellow of the Japan Society for the Promotion of Science.

called forward problem; i.e., they calculated microlens light curves based on disk models prescribed *a priori*. In contrast, we are, in the present study, concerned with a distinct approach called the inverse problem; i.e., we consider how to reconstruct the disk image (or more precisely, the emissivity distribution) of a quasar accretion disk from microlensing light curves.

For this purpose, we first simply apply the regularization method, one of the most well-known non-classical inversion techniques. The basic methodology of this method was already given by Grieger et al. (1991, hereafter GKS). Indeed, their proposed procedure has been very successful, but they have assumed rather idealized situations and, thus, there remain some problems requiring further investigation before realistic applications are obtained.

1. GKS assumed no radiation from any part outside a caustic. As a result, they could precisely determine the contribution from a small outer portion of the disk to the total light from the shape of the light curve at the beginning of a microlens event. If this were the case, we would not be able to see the disk emission in the absence of a microlensing, contrary to the observations.
2. The goal of GKS was to reconstruct a one-dimensional luminosity profile [$P(\xi)$ in their notation] which is the luminosity integrated over the disk plane in the direction parallel to that of a caustic (see figure 1 for the definition of ξ). To make a direct comparison with accretion disk models, however, it will be more convenient to express the emissivity distribution as a function of the distance from the center, $Q(r)$, since the central part of the disk can be reasonably assumed to be axisymmetric. It is thus needed to transform $P(\xi)$ to $Q(r)$.
3. GKS assumed a rather smooth emissivity distribution around the center, which certainly makes the analysis easier than otherwise. According to realistic disk models, however, it seems more likely that the emissivity has a power-law dependence on the radius, thus being sharply peaked around the center. We wish to know what fraction of the total energy output originates from a compact region in the disk.

The aim of the present study was to improve the GKS method so that it can be applied to more realistic situations. Our version of the inverse technique will be described in section 2. We then present the results of disk mapping for the calculated microlensing light curve in section 3. The final section will be devoted to a summary and discussion.

2. Inversion Procedures

Fig. 1.. Schematic view of a ‘caustic’ crossing during a microlens event. The caustic is represented by the thick vertical line, and the left-hand region corresponds to the parts inside the caustic and is subject to microlensing light amplification. One-dimensional luminosity profiles, $P_1, P_2, \dots, P_J$, are the integral of the local emissivity of the disk along the vertical lines parallel to the caustic.

2.1. Setting Matrix Forms

We first describe the regularization method adopted by GKS with some modifications.

Chang and Refsdal (1979, 1984) have shown that the flux from the bright double image of a point source close to a caustic can be amplified approximately according to $(x - \xi)^{-1/2}$, where x and ξ are, respectively, the radial distances of the caustic and that of a part of the disk in question from a line which is parallel to the caustic and which crosses the disk center (see figure 1). Note that x is time-dependent; i.e.,

$$x = x(t) = V_{\text{caus}} t / r_0, \quad (1)$$

where the unit of length, r_0 , is taken to be a typical disk dimension, $t = 0$ corresponds to the time when a caustic crosses the center of the disk, and V_{caus} is the transverse velocity of the caustic, also including that of the peculiar motion of the foreground galaxy relative to the source and the observer, on the disk plane. The total observed flux will then be approximated by

$$F(t) = F_0 \int_{-1}^1 A(x - \xi) P(\xi) d\xi. \quad (2)$$

Here, F_0 is a constant representing the total disk flux outside the caustic ($x < \xi$); i.e., $\int P(\xi) d\xi = 1$, and the amplification factor is given by

$$A(x - \xi) = \begin{cases} 1 + \frac{k}{\sqrt{x - \xi}} & \text{for } x > \xi \\ 1 & \text{for } x \leq \xi, \end{cases} \quad (3)$$

where k denotes the amplification factor inside the caustic ($x > \xi$) and depends on the spatial distribution of lensing stars and the number distribution of lens masses. Note that GKS set $A = 0$ outside the caustics and, hence, k is arbitrary, which grossly simplified the analysis. Also note that inclination effects are included in the expression of F_0 and V_{caus} (discussed later).

We assume that $P(\xi)$ is represented by a continuous, piecewise linear function,

$$P(\xi) = \frac{\xi_j - \xi}{\xi_j - \xi_{j-1}} P_{j-1} + \frac{\xi - \xi_{j-1}}{\xi_j - \xi_{j-1}} P_j \quad (4)$$

for $\xi_{j-1} \leq \xi \leq \xi_j$.

For simplicity, we take equal-distant mesh points normalized by the disk radius,

$$\xi_j = -1 + \left(j - \frac{1}{2}\right) \Delta\xi = \frac{2j - J - 1}{J} \Delta\xi \quad (5)$$

($j = 1, 2, \dots, J$),

with $\Delta\xi \equiv 2/J$, and we take the total number of mesh points (J) to be equal to that of the observed time sequences (t_i , $i = 1, 2, \dots, J$). If we set $F_i = F(t_i)$, equation (2) leads

$$\vec{F} = F_0 \mathbf{K} \vec{P} \quad \text{or} \quad F_i = F_0 \sum_{j=1}^J K_{ij} P_j \quad (6)$$

($i = 1, 2, \dots, J$)

with

$$\vec{F} = (F_1, F_2, \dots, F_J)^T, \quad \vec{P} = (P_1, P_2, \dots, P_J)^T, \quad (7)$$

and $\mathbf{K}$ being a $J \times J$ matrix given in Appendix.

2.2. Regularization Technique

It seems straightforward to derive the emissivity distribution, $P(\xi)$ or P_j ($j = 1, 2, \dots, J$), from equation (6) by calculating the inverse matrix of $\mathbf{K}$,

$$\vec{P} = \mathbf{K}^{-1}(\vec{F}/F_0). \quad (8)$$

However, this does not work efficiently, since the observational data usually contain measuring errors, which will be greatly amplified when calculating the inverse matrix (GKS).

To resolve this issue, a regularization technique was proposed. First, we express the observed flux as

$$\vec{F} = F_0 \mathbf{K} \vec{P} + \vec{\delta} \quad \text{or} \quad F_i = F_0 \sum_{j=1}^J K_{ij} P_j + \delta_i, \quad (9)$$

with δ_i being the error in measuring the flux, F_i . Next, as a measure to evaluate how the $P(\xi)$ profile is smooth we introduce a badness function,

$$L(P) = \int \left[\frac{d^2 P(\xi)}{d\xi^2} \right]^2 d\xi. \quad (10)$$

(Note that $L(P) = 0$ if $P(\xi)$ is a linear function of ξ .)

Then, the problem is reduced to determining the functional form of $P(\xi)$ which gives a minimum value of

$$[(\vec{F}/F_0) - \mathbf{K} \vec{P}]^2 + \lambda L(\vec{P}). \quad (11)$$

Namely, there are two important factors to be considered: fitting to the given light curves ($\vec{F}$, the first term) and smoothing the emissivity profile ($\vec{P}$, the second term), where $L(\vec{P})$ is the matrix form of $L(P)$,

$$L(\vec{P}) = \sum_j \left[\frac{P_{j+1} - 2P_j + P_{j-1}}{(\Delta\xi)^2} \right]^2 \Delta\xi. \quad (12)$$

The controlling parameter, λ , is called the smoothing parameter. In the limit of vanishing λ , the solution, $P(\xi)$, is given by equation (8) which can precisely reproduce the observed light curves but is not always very smooth, especially in cases with large measuring errors (GKS). In the limit of very large λ , on the other hand, the solution is smoothest, since it gives a straight line on the $[\xi, P(\xi)]$ plane, but may not give an excellent fit to the observed flux variations. We thus need to choose a moderate value of λ which satisfies

$$\frac{1}{J} \sum_{i=1}^J \left[\frac{1}{\delta_i} \left(F_i - F_0 \sum_{j=1}^J K_{ij} P_j \right) \right]^2 = 1. \quad (13)$$

In other words, the final solutions should be *as smooth as possible under the constraint that a reproduced flux variation agrees with the observed variation within the error bars*.

After some algebra, minimizing equation (11) is equivalent to setting

$$(\mathbf{K}^T \mathbf{K} + \lambda \mathbf{H}) \vec{P} = \mathbf{K}^T (\vec{F}/F_0), \quad (14)$$

where $\mathbf{H}$ is a matrix (see Appendix of GKS). The final solution, $P(\xi)$, is obtained successively by solving equation (14) for a given λ satisfying equation (13).

These procedures are performed for a specific value of k , say, $k = 0.5$ (which gives a variation with an amplitude of ~ 0.5 mag for $Q(r) \propto 1/r$). We repeat the same procedures with different values of k and determine the k -value so that $L(P)$ reaches the minimum, yielding the smoothest $P(\xi)$.

2.3. Transformation from $P(\xi)$ to $Q(r)$

As stated in Introduction, our goal is to determine the emissivity distribution of the disk as a function of r (not ξ), where r is the radial distance from the center of the accretion disk in the unit of r_0 ($r = 1$ at the outer rim). Thus, we need to transform $P(\xi)$ to $Q(r)$.

Note that the dimension of $Q(r)$ is flux; i.e., the energy emitted per unit time from a unit surface area. Then, $P(\xi)$ can be expressed as an integral of $Q(r)$ as

$$P(\xi) = \int_{-1}^1 Q(r) d\eta = 2 \int_{|\xi|}^1 Q(r) \frac{r dr}{\sqrt{r^2 - \xi^2}}. \quad (15)$$

It is of great importance to note that equation (15) takes the form of Abel's integral; that is, the inverse transformation is straightforward (see, e.g., Binney, Tremaine 1987). Since we have two independent sets of $P(\xi)$, one at $\xi < 0$ and the other at $\xi > 0$, we can separately obtain two sets of $Q(r)$, $Q^-(r)$ and $Q^+(r)$; namely,

$$Q^-(r) = \frac{1}{\pi} \int_{-\infty}^{-r} \frac{dP(\xi)}{d\xi} \frac{d\xi}{\sqrt{\xi^2 - r^2}} \quad \text{and} \\ Q^+(r) = \frac{1}{\pi} \int_r^{\infty} \left[-\frac{dP(\xi)}{d\xi} \right] \frac{d\xi}{\sqrt{\xi^2 - r^2}}. \quad (16)$$

Note that quite generally $dP/d\xi > 0$ for $\xi < 0$ and $dP/d\xi < 0$ for $\xi > 0$.

The next procedure is used to derive an expression for $Q_k^\pm = Q^\pm(r_k)$ in terms of $P_j = P(\xi_j)$ ($j = 1, 2, \dots, J$) with $r_k \equiv (2k - 1)/J$ for $k = 1, 2, \dots, J/2$. We have

$$Q^-(r_k) = \frac{1}{\pi} \sum_{j=1}^{(J/2)-k} \frac{P_{j+1} - P_j}{\sqrt{\xi_{j+(1/2)}^2 - r_k^2}} \\ + \frac{1}{\pi} \frac{P_1}{\sqrt{1 - r_k^2}} \quad (17)$$

and

$$Q^+(r_k) = \frac{1}{\pi} \sum_{j=(J/2)+k}^{J-1} \frac{P_j - P_{j+1}}{\sqrt{\xi_{j+(1/2)}^2 - r_k^2}} \\ + \frac{1}{\pi} \frac{P_J}{\sqrt{1 - r_k^2}} \quad (18)$$

with $\xi_{j+(1/2)} \equiv |(\xi_j + \xi_{j+1})/2| = (2j - J)/J$, and we used $\xi_{1/2} = -1$ and $\xi_{J+(1/2)} = +1$. We can successively find $Q^\pm(r_k)$'s for $k = 1, 2, \dots, (J/2) - 1$ from $P(\xi_j)$'s ($j = 1, 2, \dots, J$).

2.4. Producing Light Curves

To test how the above procedures work, we calculate the expected flux variations based on specific models for $Q(r)$ [hereafter denoted as $Q_{\text{model}}(r)$ to distinguish from the reconstructed values, $Q^\pm(r)$]. It is important to note that accretion disk structure can well be described as being self-similar (or more precisely, each physical quantity is expressed as a power-law function of the radius, see, e.g., Shakura, Sunyaev, 1973; Narayan, Yi 1995). We, hence, prescribe the emissivity distribution as

$$Q_{\text{model}}(r) \propto r^{-a} \quad \text{for } 0.01 \leq r \leq 1.0 \quad (19)$$

with a being a positive constant. Note that $a = 3$ for the standard-type disks, whereas $Q_{\text{model}}(r)$ is much flatter, $a \lesssim 1$, in optically-thin, advection-dominated disks (Manmoto et al. 1997).

Light curves are calculated by

$$F(t_i) = F_0 \int_0^1 r dr \int_0^{2\pi} d\theta A(x - r \cos \theta) Q_{\text{model}}(r) \\ + \delta_i \quad (20)$$

with the amplification factor $[A(x - r \cos \theta)]$ being given by equation (3). We continuously change the angular separation between the caustic and the center of the accretion disk (see Eq.[1]). The unit of time (t_0) is taken to be the crossing time over which the caustic moves on the quasar disk plane from $\xi = 0$ to $+1$. That is, $t_0 = r_0/V_{\text{caus}}$, and, hence, $x(t) = t/t_0$ from equation (1). On the intrinsic light curve, we add measuring errors, δ_i . We calculate three models for each $Q_{\text{model}}(r)$ prescription; $F(t)$ at each time is randomly fluctuated around the mean value in a Gaussian way with assumed standard deviations, Δm (in magnitude).

We plot in figure 2 how different microlens light curves are produced by changes of the $Q_{\text{model}}(r)$ prescription. The normalizations are taken so as to give $F = 1.5F_0$ at

Fig. 2.. Microlens light curves of disks whose emissivity profiles are $Q(r) \propto r^{-a}$ with $a = 0, 1, 2$, and 3 . The values of a are indicated in the figure. The larger is a , the more sharply peaked is the light curve. Note that the time of the peak flux is $t = 0$ when $a \geq 1$, but it is shifted to $t \sim 0.7t_0$ when $a = 0$.

$t = 0.1t_0$. Importantly, the peak luminosities are reached at the time of caustic crossing over the disk center ($t = 0$) only for $a \geq 1$, while a disk with a flat emissivity profile (with $a = 0$) yields the peak at a later time, $t \sim 0.7t_0$. This is because for the flat disk the amplified area (which reaches its maximum at $t = t_0$) is also an important factor. For $a \geq 1$, in contrast, the emergent flux is rather insensitive to the extent of the amplified area, since a large fraction of radiation comes from the very center of the disk.

Fig. 3.. Results of the reconstruction for the cases with $Q_{\text{model}} \propto 1/r$. The dashed curves in the lower three panels are the prescribed emissivity distribution ($Q_{\text{model}} \propto 1/r$). The solid curves in the lower panels at $r < 0$ (or $r > 0$) represent the reconstructed Q^- (Q^+) profiles calculated from $P(\xi)$ at $\xi < 0$ ($\xi > 0$) for three cases with $\Delta m = 0.1, 0.05$, and 0.02 from the left to the right, respectively. The middle panels are the prescribed $P(\xi)$ calculated from $Q_{\text{model}}(r)$, and the reconstructed ones from the light curves above. The upper three panels show the original light curves calculated by the prescribed $Q_{\text{model}}(r)$ (by the dashed lines) with error bars, and the reconstructed ones (by the solid lines).

To summarize, those cases with $a = 0$ and $a \geq 1$ give distinct flux variations. It is thus important to distinguish these two critical cases in disk mapping.

3. Results of Image Reconstruction

The results of the reconstruction are displayed in figure 3 for the case with $Q_{\text{model}}(r) \propto 1/r$. The prescribed emissivity profile is illustrated by the dashed lines in the lower three panels. To calculate the flux variation, we set a constant time interval, $\Delta t = 0.2t_0$, and the total

number of observations is $J = 24$. The calculated (i.e., ‘observed’) flux at each time is displayed together with error bars in the upper three panels by the dashed lines for different magnitudes of the mean errors, $\Delta m = 0.1$ (left), 0.05 (middle), and 0.02 (right), respectively. The dashed lines in the middle ones show the one-dimensional emissivity, $P(\xi)$, calculated from $Q_{\text{model}}(r)$.

Similarly, the reconstructed $F(t)$ and $P(\xi)$ are shown in the upper and middle panels with the solid lines. The two solid lines in the lower panels display $Q^-(r)$ at $r < 0$ and $Q^+(r)$ at $r > 0$, respectively. Note that the recon-

structed k -value does not always reproduce the original value of $k = 0.50$; we find $k = 0.61$, 0.51 , and 0.47 for $\Delta m = 0.10$, 0.05 , and 0.02 , respectively. The reconstructed flux variations and emissivity profiles are not very sensitive to these small deviations in the k -values, however.

For $a = 1$, large errors ($\Delta m = 0.1$ mag) tend to produce a rather flat $P(\xi)$ profile and thus a smooth $Q(r)$. This is because a flat model [$P(\xi) = \text{const.}$] is compatible with the light curves within the error bars so that the technique prefers a flatter $P(\xi)$ profile (see figure 2). Note again that the peak shifts from $t = 0$ in the original light curve to $t \sim 0.7t_0$ in the reconstructed one. Such a problem does not arise for those cases with smaller errors. To reproduce a steep $Q(r)$ profile up to the inner parts, $\Delta m = 0.02$ mag is necessary. It depends on the observing intervals how close to the origin the mapping technique can reproduce the original image. Surely, frequent observations, especially at around the peak flux, are preferable (GKS).

Figures 4 and 5 display the results of those cases with $Q_{\text{model}} \propto 1/r^2$, and $\propto 1/r^3$, respectively. In each figure, we omit the cases with $\Delta m = 0.05$ and $P(\xi)$ plots to avoid any complications.

Fig. 4.. Results of the reconstruction and the original for the cases with $Q_{\text{model}} \propto 1/r^2$. The lower two panels are the prescribed emissivity distribution (by the dashed lines) and the reconstructed one (by the solid lines) for two cases with $\Delta m = 0.1$ (left) and 0.02 (right), respectively. The upper two panels show the original light curves (by the dashed lines) with error bars, and the reconstructed ones (by the solid lines).

The reconstructed k -values are 0.63 ($\Delta m = 0.10$) and 0.74 ($\Delta m = 0.02$) for $a = 2$, and 0.76 ($\Delta m = 0.10$) and 0.78 ($\Delta m = 0.02$) for $a = 3$, respectively. These all deviate greatly from the original value of $k = 0.5$, particularly when a is large or Δm is small. Nevertheless,

Fig. 5.. Same as figure 4, but for cases with $Q_{\text{model}} \propto 1/r^3$.

the inner steep rise parts are reasonably well reproduced by the mapping. The wing parts are poorly reproduced for a steep $Q(r)$ profile. In fact, $Q(r)$ sometimes goes below zero. This tendency is rather enhanced for small Δm 's.

To conclude, in cases with sharply peaked emissivity profiles we can still obtain reliable information regarding the extent of the substantially emitting region, although we cannot trust the results about the outer zones surrounding the central bright zone.

4. Summary and Discussion

Let us consider specifically the case of Einstein Cross and thus insert the model parameters relevant to this source. The Einstein-ring radius on the source plane is

$$r_E \equiv \theta_E D_{\text{os}} = \left[\left(\frac{4GM_{\text{lens}}}{c^2} \right) \left(\frac{D_{\text{ls}} D_{\text{os}}}{D_{\text{ol}}} \right) \right]^{1/2} \\ \sim 1.5 \times 10^{17} \left(\frac{M_{\text{lens}}}{M_{\odot}} \right)^{1/2} \text{ cm}, \quad (21)$$

where M_{lens} is the typical mass of a lens star, and D_{ls} , D_{os} , and D_{ol} represent the angular diameter distances from lens to source, from observer to source, and from observer to lens, respectively. To evaluate these distances, we assume the redshifts corresponding to the distances from the observer to the quasar and from the observer to the lens of, $z_{\text{os}} = 1.675$ and $z_{\text{ol}} = 0.039$, respectively (see Irwin et al. 1989), and also assumed an Einstein-de Sitter universe and Hubble's constant to be $H_0 \sim 60 \text{ km s}^{-1} \text{ Mpc}^{-1}$, according to Kundić et al. (1997).

Another important length is r_{cross} , the caustic crossing length over the quasar image plane per observational time interval, Δt ;

$$r_{\text{cross}} = v_t \Delta t \frac{D_{\text{os}}}{D_{\text{ol}}} \sim 2.0 \times 10^{13} \left(\frac{v_t}{300 \text{ km s}^{-1}} \right) \left(\frac{\Delta t}{1 \text{ d}} \right) \text{ cm}, \quad (22)$$

where v_t is the transverse velocity of the lens on the lens plane ($V_{\text{caus}} \equiv v_t D_{\text{os}}/D_{\text{ol}}$). Surprisingly, this is comparable to the Schwarzschild radius, $r_g \simeq 3 \times 10^{13} (M_8)^{-1} \text{ cm}$ ($\sim 2 \text{ AU}$) for a $10^8 M_8$ black hole and is much smaller than r_E . Thus, by weekly observations can one determine the disk emissivity distributions on length scales of $\sim 10 \text{ AU}$ or $\sim 5 r_g (M_8)^{-1}$ for $v_t \sim 300 \text{ km s}^{-1}$.

To summarize, we have improved the reconstruction technique previously developed by GKS in such a way that a direct comparison with accretion disk models is possible. We have found that for deriving the emissivity distribution as a function of r on scales down to several to ten AUs, we need an accuracy of $\Delta m \lesssim 0.02 \text{ mag}$ and a sampling interval within one week. In cases in which the emissivity profile is rather centrally peaked (i.e., if $a > 1$), we can still reproduce the inner bright zone reasonably well, but cannot trust the results of the outer zone.

It might be noted that the problem treated here seems to be closely related to that of reconstructing stellar brightness profile (e.g., limb darkening) from photometry of Galactic microlensing events (see Gaudi, Gould, 1999, and references therein). The present technique may be used to analyze such data.

The inclination of the disk has two important effects. If the disk plane is tilted by an angle of i with respect to the line of sight, the apparent disk flux will be reduced by a factor of $(\cos i)^{-1}$. This affects the normalization constant, F_0 . Further, if the disk is tilted by an angle of $i_{\parallel}$ with respect to the direction of the motion of a caustic, the apparent transverse velocity of the caustic will be increased by a factor of $(\cos i_{\parallel})^{-1}$. This affects the caustic crossing, V_{caus} , and thus the time and length scales, t_0 and r_0 . In other words, the normalization constants both in the ordinate and abscissa in the (t, F) diagram and thus in the (r, Q) diagram are subject to the inclination angles. There remain ambiguities in the normalizations of r_0 and Q_0 . Since it is difficult to evaluate these inclination angles and other uncertain factors, we rather focused our effort on the shape of the non-dimensional emissivity distribution, Q/Q_0 , as a function of r/r_0 .

We must consider the fact that real photometric light curves will be unevenly sampled due to gaps in the observing schedule caused by various factors, including weather. Therefore, an even more realistic case could be made by making a model of such gaps. To see such an effect, we made a light curve in which a certain fraction, $\sim 25\%$, of the regularly spaced light curve samples

Fig. 6.. Same as figure 4, but for the unevenly sampled case. The given profile is $Q_{\text{model}} \propto 1/r$.

is removed stochastically. The results for the cases with $Q_{\text{model}} \propto 1/r$ are displayed in figure 6. The reconstructed k -values are 0.48 ($\Delta m = 0.10$) and 0.415 ($\Delta m = 0.02$), respectively. Because there are no significant changes, as long as frequent observations are made around the peak, a lack of data (uneven sampling) should not cause any serious problem. Obviously, however, poor sampling rates lead to a poor spatial resolution in the disk mapping (see equation 22). The results would sensitively depend on whether or not there are enough observation runs at the times around the peak.

HST and AXAF observations of the Einstein Cross are scheduled. If observed with multi-wavelength bands, a microlensing event should first clearly resolve the multi-wavelength radiation properties of a disk in a distant quasar on length scales down to several AUs.

The authors would like to express their thanks to Joachim Wambsganz for valuable suggestions and an anonymous referee for useful comments, which helped in making the revised version. This work was supported in part by the Grants-in Aid of the Ministry of Education, Science, and Culture of Japan (10640228, SM) and by Research Fellowships of the Japan Society for the Promotion of Science for Young Scientists, 9852 (AY).

Appendix

Equation (2) can be rewritten as

$$F_i = \sum_{j=1}^J f_{ij}, \quad (23)$$

where f_{ij} is non-zero only for $x_i > \xi_{j-1}$ and is

$$\begin{aligned} f_{ij} &= \int_{\xi_{j-1}}^{\min(\xi_j, x_i)} A(x - \xi) P(\xi) d\xi \\ &= \int_{\xi_{j-1}}^{\min(\xi_j, x_i)} \left(1 + \frac{k}{\sqrt{x_i - \xi}} \right) \\ &\quad \times \left(\frac{\xi_j - \xi}{\Delta\xi} P_{j-1} + \frac{\xi - \xi_{j-1}}{\Delta\xi} P_j \right) d\xi, \end{aligned} \quad (24)$$

with $\Delta\xi \equiv \xi_j - \xi_{j-1}$. We introduce matrices E_{ij} and D_{ij} such that

$$f_{ij} = E_{ij} P_{j-1} + D_{ij} P_j. \quad (25)$$

We then have (for $x_i > \xi_{j-1}$)

$$\begin{aligned} E_{ij} &= \frac{1}{\Delta\xi} \int_{\xi_{j-1}}^{\min(\xi_j, x_i)} \left(\xi_j - \xi + k \frac{\xi_j - \xi}{\sqrt{x_i - \xi}} \right) d\xi \\ &= \frac{1}{\Delta\xi} \int_{\Delta'\xi}^{\Delta\xi} \left(s + k \frac{s}{\sqrt{x_i + s - \xi_j}} \right) ds \\ &= \frac{1}{\Delta\xi} \left[\frac{s^2}{2} + 2ks\sqrt{x_i + s - \xi_j} \right. \\ &\quad \left. - \frac{4k}{3}(x_i + s - \xi_j)^{3/2} \right]_{\Delta'\xi}^{\Delta\xi} \\ &= \frac{(\Delta\xi)^2 - [\rho(\xi_j - x_i)]^2}{2\Delta\xi} + 2k\sqrt{x_i - \xi_{j-1}} \\ &\quad - \frac{4k}{3} \frac{(x_i - \xi_{j-1})^{3/2} - [\rho(x_i - \xi_j)]^{3/2}}{\Delta\xi}, \end{aligned} \quad (26)$$

with $s \equiv \xi_j - \xi$, $\Delta'\xi \equiv \rho(\xi_j - x_i)$ and

$$\rho(x_i - \xi_j) \equiv \begin{cases} x_i - \xi_j & \text{for } x_i > \xi_j \\ 0 & \text{for } x_i \leq \xi_j. \end{cases} \quad (27)$$

Similarly, we find (for $x_i > \xi_{j-1}$)

$$\begin{aligned} D_{ij} &= \frac{1}{\Delta\xi} \int_{\xi_{j-1}}^{\min(\xi_j, x_i)} \left(\xi - \xi_{j-1} + k \frac{\xi - \xi_{j-1}}{\sqrt{x_i - \xi}} \right) d\xi \\ &= \frac{1}{\Delta\xi} \int_0^{\Delta''\xi} \left(u + k \frac{u}{\sqrt{x_i - u - \xi_{j-1}}} \right) du \\ &= \frac{1}{\Delta\xi} \left[\frac{u^2}{2} - 2ku\sqrt{x_i - u - \xi_{j-1}} \right. \\ &\quad \left. - \frac{4k}{3}(x_i - u - \xi_{j-1})^{3/2} \right]_0^{\Delta''\xi} \\ &= \frac{(\Delta''\xi)^2}{2\Delta\xi} - 2k \frac{\Delta''\xi}{\Delta\xi} \sqrt{\rho(x_i - \xi_j)} \\ &\quad + \frac{4k}{3} \frac{(x_i - \xi_{j-1})^{3/2} - [\rho(x_i - \xi_j)]^{3/2}}{\Delta\xi}, \end{aligned} \quad (28)$$

with $u \equiv \xi - \xi_{j-1}$ and $\Delta''\xi \equiv \min(\Delta\xi, x_i - \xi_{j-1})$. For $x_i \leq \xi_{j-1}$ both are zero, $E_{ij} = D_{ij} = 0$. Since we have from equation (25)

$$f_{ij} = (E_{i,j+1} + D_{ij}) P_j \equiv K_{ij} P_j, \quad (29)$$

for $(i, j) = (1, 1), (1, 2), \dots, (J, J)$, it is straightforward to derive expression for $\mathbf{K}$,

$$K_{ij} = E_{i,j+1} + D_{ij}, \quad (30)$$

by inserting equations (26) and (28).
